

percolation on finite graphs

Itai Benjamini

January 16, 2001

Abstract

Several questions and few answers regarding percolation on finite graphs are presented.

The following is a note regarding the asymptotic study of percolation on finite transitive graphs. On the one hand, the theory of percolation on infinite graphs is rather developed, although still with many open problems (See [9]). On the other hand random graphs were deeply studied (see [7]). Finite transitive graphs are somewhat in the middle. Though a big part of the picture is similar to the percolation on infinite graphs theory, some qualitative phenomena are different and provides new challenges.

Recall that a graph G is transitive iff for every two vertices $v, u \in G$, there is an isomorphism of G , mapping v to u . See [4] or [9] for further background and definitions.

Given a finite graph G , delete edges from G independently, each with probability $1 - p$. Denote by $p^G = p_{1/2}^G$, the threshold probability for having a connected component of size $|G|/2$. I.e.,

$$\mathbf{P}_{p^G}(\text{There is a connected component of size } \geq |G|/2) = 1/2.$$

Note that for transitive graphs the threshold for having a large connected component is sharp [5]. Write p_α^G for the threshold probability for having a component of size $\alpha|G|$, with probability $1/2$.

1 Giant component

A giant component theorem will be proven under a weak concentration of measure assumption. A family of graphs G_n , $|G_n| \nearrow \infty$, admits a weak concentration of measure, if for every $C > 0$, and every two sets of vertices $A_n, B_n \subset G_n$, $|A_n|, |B_n| \geq C|G_n|$,

$$d(A_n, B_n) = o(\text{diameter}(G_n)).$$

Assume also that $\text{diameter}(G_n) \leq C \log |G_n|$ and that K is a uniform upper bound on the degrees of G_n .

Theorem 1.1. *Let G_n is a sequence of graphs satisfying the conditions above, then for every $\epsilon > 0$ and $0 < C < 1$,*

$$\mathbf{P}_{p^{G_n+\epsilon}}(\text{There is a unique connected component of size } \geq C|G|) \longrightarrow 1,$$

as n goes to infinity.

Proof. It is enough to show that given any two set $A_n, B_n \subset G_n$, $|A_n|, |B_n| \geq C|G_n|$, $C > 0$, and $\epsilon > 0$, if we do ϵ percolation on G_n , there will be an open path from A_n to B_n , with probability going to 1, with n . We will show that there are an exponential number, in the $\text{diameter}(G)$, edge disjoint paths of length $o(\text{diameter}(G))$ connecting A_n to B_n . Indeed for every vertex in A_n look at it's shortest paths to B_n , as n grows for most of the vertices of A_n their shortest path to B_n , has length which is $o(\text{diameter}(G))$, so we get a set of paths of size bigger than $|A_n|/2$, with length much smaller than the diameter, denoted by l_n . Now for a fixed l , the number of paths of length l , that intersects a paths of length m in G_n , is bounded by $m \times K^l$. Which implies that there are more than,

$$\frac{|A_n|}{2l_n \times K^{l_n}}$$

disjoint paths of length smaller than l_n between A_n and B_n . Each path has probability $\geq \epsilon^{l_n}$ to be open, independently from the other paths. The probability of having no open paths is bounded then by,

$$(1 - \epsilon^{l_n})^{\frac{|A_n|}{2l_n \times K^{l_n}}}.$$

Pick n large to finish. □

The above concentration condition is clearly satisfied by expanders and other families of graphs, but not by all transitive graphs of logarithmic diameter. E.g., let G'_n be the product $G_n \times C_{\text{diameter}(G_n)}$, where C_n is a cycle of length n , and G_n satisfy the above assumptions.

One would expect that concentration of measure is not necessary, but then we assume that the graphs are transitive.

Conjecture 1.2. *Assume G_n is a sequence of finite transitive graphs with $|G_n| \nearrow \infty$. Then for every $\epsilon > 0$ and $C > 0$,*

$$\mathbf{P}_{p^{G_n+\epsilon}}(\text{There is a unique connected component of size } \geq C|G|) \longrightarrow 1,$$

as n goes to infinity.

The conjecture is true for a large Euclidean torus by the Grimmett-Marstrand theorem [6].

The following proposition (due to Oded) is of independent interest. Consider percolation on a finite Cayley graph,

Proposition 1.3. *Assume*

$$\mathbf{P}_p(v \text{ is in a connected component of size } \geq C|G|) = q.$$

Then for every $u \in G$,

$$\mathbf{P}_p(v \text{ and } u \text{ are in the same connected component}) \geq (Cq/2)^{6/qC}.$$

Proof. The expected number of vertices v is connected to, is bigger or equal to $qC|G|$. Thus there are more than $qC|G|/2$ vertices u which are connected to v with probability $\geq qC/2$. Let S be the set of these vertices. S is symmetric and generating, since it contains v neighbors. By FKG it is enough to show that the diameter of the group using S as a generating set is bounded by $6/qC$. Assume $a_1 a_2 \dots a_l$ is a shortest word, in the generators S , representing an element of the group. It follows that for any k and l , divisible by 3, $a_1 a_2 \dots a_k g \neq a_1 a_2 \dots a_l g'$ for any $g, g' \in S$. Otherwise one can reduced the length of the word. We get that $l/3 \times |S| \leq |G|$ i.e. $l \leq 6/qC$. $\square$

2 Threshold bounds

In light of the theorem and the conjecture, (which suggests a further study in the spirit of random graphs theory, e.g., components size and scaling around the birth of the giant component etc. see [7]), it will be useful to have upper bounds on p^G , guaranteeing the threshold is not converging to 1. The techniques mentioned in this section are similar to the infinite graphs case.

[2] gives a bound in terms of the length of the longest relation in the presentation of the group. Theorem 2 in [4] can be adapted to finite graphs, and will provide a bound in terms of the isoperimetric constant of the graph, guaranteeing that the threshold is not converging to 1 for expanders. These bounds together do not provide a sharp condition for boundedness away from 1. We suspect the following condition is sharp.

Conjecture 2.1. *Assume that G is a transitive graph. There is a constant $C < 1$, so that if*

$$\text{diameter}(G) < \frac{|G|}{\log |G|},$$

then $p^G < C$.

Maybe the classification theorem for simple groups can be useful in attacking the conjecture, even just for Cayley graphs. A good start might be Cayley graphs of S_n .

One way to prove an upper bound on the threshold for a graph G , is to find a known percolating graph spanning a linear portion of G . Another is to use measures on paths with exponential intersection tail (*EIT*).

Say a graph G , has the *EIT*(c), $0 < c < 1$, property iff for any two vertices $u, v \in G$, there is a set of paths, S_{uv} , from v to u , and a measure on the paths so that if you pick two paths independently at random from S_{uv} , then the probability that the two paths will have more than k intersections decays faster than c^k .

A second moment argument (done in the infinite graph setting in [3]) implies that if G has the *EIT*(c) property, for some $c < 1$, the threshold for giant component will be bounded away from 1.

Oriented paths on $\mathbb{Z}^4$, provide a family of such paths for $(\mathbb{Z}/n\mathbb{Z})^4$. (For $(\mathbb{Z}/n\mathbb{Z})^3$, it is harder to construct paths with exponential intersection tail, and appears in [3].

Conjecture 2.2. *Let G be a finite transitive graph. There is $0 < c < 1$, such that if*

$$\text{diameter}(G) < |G|^{1/3},$$

then G admits the $EIT(c)$ property.

Adaptation of the argument in [8] gives that if $\text{diameter}(G) < C \log |G|$, then G admits the $EIT(c)$ property (with c depending on C).

If conjecture 2.2 is true, it will also imply the following a bit unrelated conjecture.

Conjecture 2.3. *Let G be a finite transitive graph. There is $R < \infty$, such that if*

$$\text{diameter}(G) < |G|^{1/3},$$

then the effective electric resistance between any two vertices in G is smaller than R .

A natural conjecture sharpening theorem 2 of [4] is as follows. Given a graph G , let

$$\delta(G) = \sup\{\alpha \mid |\partial S| \geq |S|^\alpha, \text{ for all } S \subset G, |S| \leq |G|/2\}.$$

Conjecture 2.4. *If $\delta(G) > \delta > 0$, then $p^G < f(\delta) < 1$.*

3 Percolation implies giant component?

Conjecture 2.1 above is a finite analog of the still open conjecture from [4], that the critical percolation probability is strictly smaller than 1 on infinite Cayley graphs of groups which are not finite extension of $\mathbb{Z}$. We now move to discuss the percolation probability function.

Note that in [2] it was conjectured that there are no infinite connected component for critical percolation on infinite transitive graphs and one expect that the percolation probability function should be continuous, (see [11]). It is therefore natural to conjecture that for a sequence of finite transitive graphs $G_n \longrightarrow G$, then for any $0 < \alpha_1 < \alpha_2 < 1$,

$$p_{\alpha_1}^{G_n} - p_{\alpha_2}^{G_n} \rightarrow c > 0.$$

I.e. the thresholds for connected component of different proportion stay apart. In the last section we discussed bounds on p^G , i.e. birth of a component of half the size. In this section we discuss the birth of components of linear size.

Assume the transitive graphs G_n converges weakly to the infinite graph G and $\{p^{G_n}\}_n$ are bounded away from 1. Let $\theta_n(p)$ be the probability a fixed vertex is in the largest component, and $\theta(p)$ be the probability a fixed vertex in G is in an infinite cluster. As usual $p_c(G)$ is critical probability for percolation on G .

Question 3.1. *Does*

$$\theta_n(p) \longrightarrow \theta(p)?$$

And in particular

$$\lim_{\alpha \rightarrow 0} \lim_n p_\alpha^{G_n} = p_c(G)?$$

For example, assume G_n has growing girth and all vertices has the same degree, say 3, and $\{p^{G_n}\}_n$ are bounded away from 1. Hence $G_n \longrightarrow T_3$, the 3-regular tree. Recall that $p_c(T_3) = 1/2$, that is the critical probability for percolation on T_3 is $1/2$. We have,

Conjecture 3.2. *For every $p > 1/2$ there is some $C_p > 0$, such that*

$$\mathbf{P}_p(\text{There is a unique connected component of size } C_p |G_n|) \longrightarrow 1,$$

as $n \longrightarrow \infty$.

An example that supports the conjecture is as follows, start with a cycle of n vertices. Pick uniformly a random matching between the vertices on the cycle. Add an edge between any matched pair. Around a typical vertex this graph (a typical sample) looks like a regular tree for more than $1/10 \log n$ generations, and indeed as n grows the threshold for the existence of a giant component goes to $1/2$.

Of independent interest, we expect the largest components at the threshold to be of size $O(n^{2/3})$ as in the critical random graphs $G(n, 1/n)$ and probably in critical percolation on expanders. In particular we conjecture that for percolation with $p = (k-1)^{-1}$ on a random k -regular graph (that's the threshold). The largest components is of size $O(n^{2/3})$.

Another supporting example is the theorem in [1] asserting that the threshold for a giant component on the hypercube $\{0,1\}^d$, is $1/d$. Conjecture 3.1 is true for a large Euclidean torus by the Grimmett-Marstrand theorem [6].

Note that, if B_n are growing balls in a nonamenable Cayley graph G , assuming the conjecture (from [4]) that $p_c(G) < p_u(G)$, then the threshold for connected component of linear size in B_n will converge to p_u rather than p_c .

Intuitively the content of the last two conjectures is as follows: On infinite transitive graph percolation means having unbounded connected components, and uniqueness of the infinite cluster is the analog of existence of a giant component. We doubt, whether on finite transitive graphs component of large diameter can occur and moreover contain portion of the vertices, without having a giant component. One informal reason we have, is that unlike infinite graphs (e.g. regular trees) finite transitive graphs do not have bottlenecks, unless they contain an irreducible cycle, proportional in size to the graphs, (as in $C_n \times G$, where C_n are growing cycles and G is a fixed finite graph). An argument using flows (see for instance [10]) gives that the Cheeger constant of a finite transitive graph, $h(G)$, satisfies $h(G) \geq \text{diameter}^{-1}(G)$.

Remark: (On limits of transitive graphs, by Russ and Yuval) Every weak limit of finite transitive graphs (or even of unimodular infinite transitive graphs) is unimodular transitive. This is from the fact that there is a unimodular group acting transitively on the limit graph, namely, the group of automorphisms that arise as limits of automorphisms. This group is unimodular by the criterion of Trofimov [12].

Let us end by saying that there are further directions to pursue, e.g., compare mixing times of random walks on the giant component to mixing times on the graph. Maybe one should start with a further study of the geometry of finite transitive graphs e.g., what asymptotic diameters possible for finite transitive graphs, or cutsets structure.

Acknowledgments: Thanks to Russell Lyons, Igor Pak, Yuval Peres and Oded Schramm for useful discussions.
